We explore the explanation of the Fermi Galactic Center Excess (GCE) in the Next-to-Minimal Supersymmetric Standard Model. We systematically consider various experimental constraints including the Dark Matter (DM) relic density, DM direct detection results and indirect searches from dwarf galaxies. We find that, for DM with mass ranging from 30 GeV to 40 GeV, the GCE can be explained by the annihilation $\chi\chi \rightarrow a^* \rightarrow b\bar{b}$ only when the CP-odd scalar satisfies $m_a \simeq 2m_\chi$, and in order to obtain the measured DM relic density, a sizable Z -mediated contribution to DM annihilation must intervene in the early universe. As a result, the higgsino mass μ is upper bounded by about 350 GeV. Detailed Monte Carlo simulations on the $3\ell + E_T^{miss}$ signal from neutralino/chargino associated production at 14-TeV LHC indicate that the explanation can be mostly (completely) excluded at 95% C.L. with an integrated luminosity of 100(200) fb^{-1} . We also discuss the implication of possible large Z coupling to DM for the DM-nucleon spin dependent (SD) scattering cross section, and find that although the current experimental bounds on σ_p^{SD} is less stringent than the spin independent (SI) results, the future XENON-1T and LZ data may be capable of testing most parts of the GCE-favored parameter region.

I. INTRODUCTION

As a building block of the universe, Dark Matter (DM) is a focus of current particle physics. The existence of a Weakly Interacting Massive Particle as a DM candidate has been indicated by some direct detection experiments like DAMA/LIBRA [1], CoGeNT [2, 3], CRESST [4] and CDMS [5], although these results are not consistent with each other very well and not supported by other experiments such as Xenon [6] and LUX [7]. On the other hand, indirect DM searches also reported some anomalies. Recent data analyses of the Large Area Telescope (LAT) onboard the Fermi Gamma-ray Space Telescope have shown an excess around 1 \sim 4 GeV in the photon energy spectrum coming from the Galactic Center [8–17]. It has been shown that this excess can be well explained by a \sim 35 GeV DM annihilating 100% into $b\bar{b}$ with a thermal averaged cross section of about $2 \times 10^{-26} \text{ cm}^3/\text{s}$, which is remarkably close to the value required by the measured relic density Ωh^2 [13, 16].

So far several works have studied such a Galactic Center Excess (GCE) in supersymmetry [18–24]. It was found that after considering the constraints from the Ωh^2 , the most promising DM annihilation channel is $\chi\chi \rightarrow a^* \rightarrow b\bar{b}$ where a is a CP-odd Higgs boson lighter than about 100 GeV. In the Minimal Supersymmetric Standard Model (MSSM), due to the mass correlation between the pseudoscalar and the charged/heavy CP-even scalar, the pseudoscalar is generally heavier than about 300 GeV and thus cannot explain the GCE. In the Next-to-MSSM (NMSSM), an extra singlet superfield \hat{S} is introduced, which results in three CP-even Higgs bosons $h_{1\sim 3}$, two CP-odd Higgs bosons $a_{1,2}$ and five neutralinos $\tilde{\chi}_{1\sim 5}^0$ (an ascending mass order for the same type of particles is assumed, with $\tilde{\chi}_1^0$ acting as DM and denoted by χ hereafter) [25]. Since the CP-odd Higgs boson a_1

may be singlet-like and rather light, light DM pair can annihilate mainly through the s -channel mediation of a_1 in both the early universe and today if $m_{a_1} \simeq 2m_\chi$. As shown in [21], in NMSSM a bino-like DM can explain both the GCE and the Ωh^2 through an off-shell a_1 , while a singlino-like DM requires a tuned resonance $2m_\chi \simeq m_{a_1}$ to achieve the same goal.

In this work we intend to interpret the GCE with a \sim 35 GeV DM in the NMSSM. Compared with previous works, we consider more constraints (such as current Higgs data) on the model. We note that taking into account the uncertainties of DM profile in the Galaxy as well as the astrophysical uncertainties of background and foreground will result in a wide range of DM annihilation cross sections which can accommodate the GCE [26, 27], e.g. $\langle\sigma v\rangle|_{v\rightarrow 0} = (0.4 \sim 5.0) \times 10^{-26} \text{ cm}^3/\text{s}$. However, the observation of dwarf galaxies as well as other comic ray fluxes such as positron and antiproton are capable of setting upper limits on the cross sections of DM annihilation into various channels [28–34]. Taking DM annihilation into $b\bar{b}$ as an example, the Fermi observation of dwarf galaxies has required $\langle\sigma v\rangle|_{v\rightarrow 0} \lesssim 1.3 \times 10^{-26} \text{ cm}^3/\text{s}$ for $m_{\text{DM}} = 35 \text{ GeV}$ [30, 31]. So if we consider the constraint from the dwarf galaxies and ignore possibly stronger constraints from other comic ray observations [32–34], a reasonable DM annihilation rate dominated by $b\bar{b}$ channel can be chosen to be in the range of $\langle\sigma v\rangle|_{v\rightarrow 0} = (0.4 \sim 1.3) \times 10^{-26} \text{ cm}^3/\text{s}$ to explain GCE. With these considerations we obtained different observations from those in [21], e.g. we found that a singlino-like DM instead of a bino-like DM is easier to explain both the GCE and the correct Ωh^2 . More importantly, we observed that $\chi\chi \rightarrow a_1^* \rightarrow b\bar{b}$ can not alone explain both the GCE and the Ωh^2 , and in order to get the correct Ωh^2 , a sizable s -channel Z contribution to the early DM annihilation is usually needed. Consequently, the higgsino mass μ is

upper bounded by about 350 GeV, which will be readily tested at the LHC Run-II through the trilepton signal of neutralino/chargino associated production. We also discuss another interesting aspect of this GCE-motivated scenario, i.e. the implication of possible large Z coupling to DM for the DM-nucleon spin dependent (SD) scattering cross section, which did not receive much attention in previous works.

This paper is organized as follows. In Section II we describe the basic features of NMSSM and our scan strategies. In Section III we present our results and discussions. Finally we conclude in Section IV.

II. MODEL AND SCAN STRATEGIES

The superpotential of the NMSSM is given by [25]

$$W^{\text{NMSSM}} = W_F + \lambda \hat{H}_u \cdot \hat{H}_d \hat{S} + \frac{1}{3} \kappa \hat{S}^3,$$

where W_F is the MSSM superpotential without the μ -term, \hat{H}_u and \hat{H}_d are MSSM Higgs superfields, λ and κ are coupling coefficients for Higgs superfields. The corresponding Higgs potential is then parameterized by soft breaking masses $\tilde{m}_{u,d,s}^2$ for Higgs fields $H_{u,d,s}$ and trilinear soft breaking coefficients A_λ and A_κ . In this framework, the CP-even (odd) Higgs mass eigenstates are mixtures of the real (imaginary) parts of H_u , H_d and s , and the neutralino mass eigenstates are the mixtures of bino, wino, higgsinos and singlino. In practice, the parameters $\tilde{m}_{u,d,s}^2$ are traded for m_Z , $\tan\beta \equiv v_u/v_d$ and $\mu \equiv \lambda v_s$ as theoretical inputs.

In our analysis, we fix all soft masses and soft trilinear parameters in squark (slepton) sector at 2 (0.3) TeV except that we allow the soft trilinear couplings $A_t = A_b$ to vary to obtain a ~ 125 GeV CP-even Higgs. In order to get a light bino-like DM, we abandon the GUT relation among gaugino masses and set wino mass $M_2 = 1$ TeV and gluino mass $M_3 = 2$ TeV. Thus the free parameters are $\tan\beta$, μ , λ , κ , A_λ , A_κ in the Higgs sector, bino mass M_1 and A_t , which are all defined at 2 TeV. We adopt the Markov Chain Monte Carlo method to scan following parameter space with `NMSSMTools-4.3.0` [35]:

$$\begin{aligned} 1 < \tan\beta < 40, \quad 0 < \lambda < 0.7, \quad 0 < |\kappa| < 0.7, \\ 0 < |A_\kappa| < 2 \text{ TeV}, \quad 0 < A_\lambda < 5 \text{ TeV}, \quad |A_t| < 5 \text{ TeV}, \\ 0 < |M_1| < 0.6 \text{ TeV}, \quad 0.1 \text{ TeV} < \mu < 0.6 \text{ TeV}. \end{aligned} \quad (1)$$

We select the samples by following steps: we require $30 \text{ GeV} \leq m_\chi \leq 40 \text{ GeV}$ and impose all constraints encoded in the `NMSSMTools-4.3.0` including the relic density at 3σ level (corresponding to $0.107 \leq \Omega h^2 \leq 0.131$), LUX exclusion limit at 90% C.L. and various B-physics measurements with criteria described in detail in [36]. Then we use `HiggsBounds-4.1.2` [37] to systematically impose the constraints from Higgs searches at LEP, Tevatron and LHC. We also perform a fit to the Higgs data updated in the summer of 2014 with details described in [38]

TABLE I. Expected cross sections of the SM background after cuts for fix signal regions in [40] and the SRZd region defined in this work at 14-TeV LHC.

	Expected cross section (fb)						
	SRnoZa	SRnoZb	SRnoZc	SRZa	SRZb	SRZc	SRZd

$Z^{(*)}W^{(*)}$	4.33	1.96	0.23	22.28	2.06	0.58	0.24
$t\bar{t}$	4.97	1.31	0.28	0.90	0.11	0.06	0.00
Total	10.62	3.47	0.54	24.08	2.29	0.68	0.25

and keep the 2σ samples with $\Delta\chi^2 = \chi^2 - \chi_{min}^2 < 6.18$. Subsequently we calculate the DM annihilation cross section today with `micrOMEGAs-3.6.9.2` [39] and keep the samples with $\langle\sigma v\rangle|_{v\rightarrow 0} = (0.4 \sim 1.3) \times 10^{-26} \text{ cm}^3/\text{s}$ to explain GCE.

We find that the surviving samples are characterized by $9 < \tan\beta < 33$, $170 \text{ GeV} < \mu < 350 \text{ GeV}$ and $m_{h^\pm} > 500 \text{ GeV}$. We classify them into four scenarios: for scenario I-S (I-B), h_1 corresponds to h_{SM} and DM is singlino(bino)-like, while for scenario II-S (II-B), h_2 acts as h_{SM} with DM being singlino(bino)-like. Since the higgsino mass μ of the surviving samples is not very large, they should be testable at 14-TeV LHC through the channel $pp \rightarrow \tilde{\chi}_i^\pm \tilde{\chi}_j^0 \rightarrow 2\tilde{\chi}_1^0 W Z \rightarrow 3\ell + E_T^{\text{miss}}$ where $i = 1, 2$ and $j = 1 \sim 5$ [40]. For each sample we perform a simulation, in which we use `MadGraph5` [41] and `Pythia` [42] to generate relevant events and evaluate the parton shower. With `Delphes` [43] encoded in `CheckMATE-1.16` [44], we obtain the cut efficiencies for the six signal regions (SRs) of [40]. Then we calculate $\sigma(pp \rightarrow \tilde{\chi}_i^\pm \tilde{\chi}_j^0)$ with `Prospino2` [45] at next-to-leading order and evaluate the significance $\mathcal{S} = s/\sqrt{b + (10\%b)^2}$ for each SR, where s and b correspond to the number of signal and background events after cuts and 10% is the assumed systematical uncertainty of the backgrounds. Moreover, in order to probe the moderately large μ region more efficiently, besides the six SRs in [40] we consider one more SR named SRZd, which has the same cuts as SRZc in [40] except that it requires $E_T^{\text{miss}} > 165 \text{ GeV}$. In Table.I, we list our backgrounds after cuts in different SRs. We also performed similar analysis of the trilepton signal at 8-TeV LHC and found no limits on the surviving samples.

III. RESULTS AND DISCUSSION

A. Scan results: Among the four scenarios to explain both the GCE and the Ωh^2 in the allowed parameter space, we find that II-S is most favored, and II-B and I-B are marginally okay by tuning the relevant parameters (we only get a few benchmark points after a long time scan), while we cannot find any I-S sample. We present several benchmark points of the three available scenarios, and show their details in Table.II.

To understand why scenario II-S is most favored by the GCE, we start with an effective Lagrangian [21, 46–48]

$$-\mathcal{L}_{\text{int}} = iy_{a_1\chi\chi} a_1 \bar{\chi} \gamma^5 \chi + iy_{a_1 b\bar{b}} a_1 \bar{b} \gamma^5 b, \quad (2)$$

TABLE II. Benchmark points for scenario II-S, II-B and I-B, respectively. Quantities with mass dimension are in unit of GeV and the DM annihilation cross section is in unit of cm^3/s . The scattering cross sections in direct detection are in unit of pb.

where $y_{a_1\chi\chi}$ and $y_{a_1b\bar{b}}$ are Yukawa couplings. The cross section for the annihilation $\chi\chi \rightarrow a_1^* \rightarrow b\bar{b}$ is given by

$$\langle\sigma v\rangle_{b\bar{b}}|_{v\rightarrow 0} \propto \frac{y_{a_1\chi\chi}^2 y_{a_1b\bar{b}}^2 m_\chi^2}{(4m_\chi^2 - m_{a_1}^2)^2 + m_{a_1}^2 \Gamma_{a_1}^2}. \quad (3)$$

This formula indicates that in order to predict a relatively large $\langle\sigma v\rangle_{b\bar{b}}|_{v\rightarrow 0}$, either $y_{a_1\chi\chi}y_{a_1b\bar{b}}$ takes a sufficiently large value or m_{a_1} approaches to $2m_\chi$. In NMSSM, the experimental bounds we considered have limited a_1 to be highly singlet-like (so Γ_{a_1} is very small), and $m_{a_2} \gtrsim 500$ GeV. Consequently, $y_{a_1\chi\chi}$ in scenario II-S mainly gets contribution from the superpotential term $\kappa \hat{S}^3$ and is approximately $\sqrt{2}\kappa$ [25]. In contrast, since DM is bino-like in scenarios II-B and I-B, $y_{a_1\chi\chi}$ is suppressed by a factor $\lambda(m_Z \sin\theta_W/\mu)^2(m_\chi/\mu)$ with θ_W being the weak mixing angle [21]. Since $y_{a_1\chi\chi}$ in scenario II-S can be much larger than those in scenarios II-B and I-B, m_{a_1} in scenario II-S may slightly deviate from $2m_\chi$ while being capable of explaining the GCE so that the theory is less tuned (see Table.II). We emphasize that all the three scenarios require a low μ : in scenario II-S, a low μ is needed to predict $m_{h_2} \simeq 125$ GeV [49], while in scenarios II-B and I-B, a low μ is necessary to keep $y_{a_1\chi\chi}$ moderately large.

Finally we discuss scenario I-S, which is featured by $2\kappa v_s \sim 35$ GeV to get the desired DM mass and the CP-even singlet Higgs mass $|M_{S,33}| > 125$ GeV to ensure h_1 being h_{SM} . Furthermore, to explain the GCE $\tan\beta \gtrsim 10$ is usually needed to enhance the coupling $y_{a_1b\bar{b}}$, and the singlet-like a_1 should be around $2m_\chi$, which corresponds to the CP-odd singlet Higgs mass $|M_{P,22}| \sim 70$ GeV. However, from the expressions of $M_{S,33}^2$ and $M_{P,22}^2$ [25]

$$M_{S,33}^2 = \lambda A_\lambda \frac{v_u v_d}{v_s} + \kappa v_s (A_\kappa + 4\kappa v_s),$$

$$M_{P,22}^2 = \lambda (A_\lambda + 4\kappa v_s) \frac{v_u v_d}{v_s} - 3\kappa v_s A_\kappa,$$

one learns that the appropriate values of $|M_{S,33}|$ and $|M_{P,22}|$ are very difficult to obtain simultaneously for a

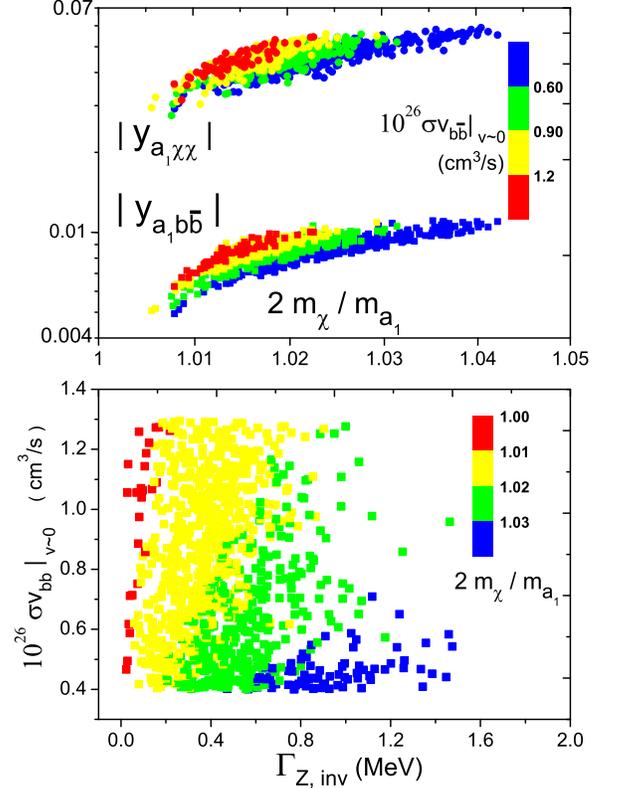

FIG. 1. The dependence of $y_{a_1\chi\chi}, y_{a_1b\bar{b}}$ (upper panel), $\langle\sigma v\rangle_{b\bar{b}}|_{v\rightarrow 0}, \Gamma_{Z,inv}$ (lower panel) on $2m_\chi/m_{a_1}$ for surviving samples in scenario II-S.

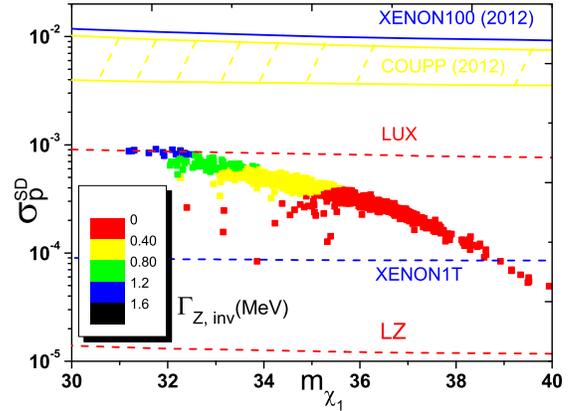

FIG. 2. DM mass m_χ versus DM-nucleon SD scattering cross section σ_p^{SD} for II-S samples. Various experimental upper limits are taken from [51].

usually negative κA_κ (see Eq.(C.10) of [21]). In the rest of this work, we will mainly focus on scenario II-S. For scenario I/II-B, we will only briefly describe their features since delicate tuning is needed in these scenarios.

B. DM annihilation in the early universe: From

Table.II one learns that the three benchmark points all have $2m_\chi/m_{a_1} > 1$, which means that the present DM annihilation $\langle\sigma v\rangle|_{v\rightarrow 0}$ is usually larger than that at freezing out $\langle\sigma v\rangle_0$ due to the thermal broadening if DM annihilates only through the intermediate a_1 . However, in order to predict the measured Ωh^2 , $\langle\sigma v\rangle_0$ should be around the canonical value $3 \times 10^{-26} \text{ cm}^3/\text{s}$. Since the dwarf galaxy measurements have required $\langle\sigma v\rangle_{b\bar{b}}|_{v\rightarrow 0} \lesssim 1.3 \times 10^{-26} \text{ cm}^3/\text{s}$, $\chi\chi \rightarrow Z^* \rightarrow b\bar{b}$ must also contribute sizably to the annihilation in the early universe. A good way of illustrating this is to observe the Z boson invisible decay width into DM pair $\Gamma_{Z,inv}$ which contains the coupling of Z boson to DM pair.

As stated above, in the following we concentrate on the samples of scenario II-S. In the upper and lower panels of Fig.1, we show $y_{a_1\chi\chi}$ and $y_{a_1b\bar{b}}$ as a function of $2m_\chi/m_{a_1}$ and the correlation between $\langle\sigma v\rangle_{b\bar{b}}|_{v\rightarrow 0}$ and $\Gamma_{Z,inv}$, respectively. The upper panel indicates that as $2m_\chi/m_{a_1}$ increases, $y_{a_1\chi\chi}$ and $y_{a_1b\bar{b}}$ must also increase to maintain an appropriate $\langle\sigma v\rangle_{b\bar{b}}|_{v\rightarrow 0}$ to explain the GCE. This panel also shows that for a fixed $y_{a_1\chi\chi}$ or $y_{a_1b\bar{b}}$, generally a $2m_\chi/m_{a_1}$ closer to 1 corresponds to a larger $\langle\sigma v\rangle_{b\bar{b}}|_{v\rightarrow 0}$ since the cross section in Eq.(3) is very sensitive to the resonance. One can also clearly see that for a fixed $2m_\chi/m_{a_1}$, increasing $y_{a_1\chi\chi}$ and/or $y_{a_1b\bar{b}}$ will help to obtain a larger $\langle\sigma v\rangle_{b\bar{b}}|_{v\rightarrow 0}$ as expected.

The lower panel indicates that very close to the resonance region (e.g. red samples with $2m_\chi/m_{a_1} < 1.01$) $\Gamma_{Z,inv}$ is quite small, generally in the range of $\Gamma_{Z,inv} < 0.2 \text{ MeV}$, which means $\chi\chi \rightarrow Z^* \rightarrow b\bar{b}$ contribution to $\langle\sigma v\rangle_0$ is limited. As $2m_\chi/m_{a_1}$ departs from the resonance one usually has an increased $\Gamma_{Z,inv}$ and decreased $\langle\sigma v\rangle_{b\bar{b}}|_{v\rightarrow 0}$, which is most obvious for $2m_\chi/m_{a_1} > 1.03$. This is because in the resonance region, the correlation between the a_1 contributions to $\langle\sigma v\rangle_0$ and to $\langle\sigma v\rangle|_{v\rightarrow 0}$ is relatively weak [50] and both can be quite large, in which case the Z contribution to $\langle\sigma v\rangle_0$ can be small. When a_1 is off-shell, however, the correlation becomes strong and the thermal broadening makes a_1 contribution to $\langle\sigma v\rangle_0$ get locked to be less than its contribution to $\langle\sigma v\rangle|_{v\rightarrow 0}$ which is already smaller than the required canonical value. Consequently, a sizable Z contribution must be present in the early universe. Note that in order to obtain a sizable Z contribution which requires a moderately large coupling $g_{Z\chi\chi}$, μ can not be too large since $g_{Z\chi\chi} \propto (\lambda v/\mu)^2$ for singlino-like DM and $g_{Z\chi\chi} \propto (m_Z \sin\theta_W/\mu)^2$ for bino-like DM [21]. As shown in Fig.1, a sizable Z contribution allows $2m_\chi/m_{a_1}$ to deviate moderately from 1 to make scenario II-S less tuned.

Finally we would like to comment briefly on the case of $2m_\chi/m_{a_1} < 1$, where the DM annihilation in the early universe can benefit from the thermal average over the resonance effect of a_1 . As we mentioned below Eq.(3), the highly singlet-like a_1 with a very small width will make the resonance effect quite significant [50]. In this case, the relic density forbids the parameter region with very strong resonance, e.g. $0.9 \lesssim 2m_\chi/m_{a_1} \lesssim 1$ [21], and consequently the a_1 -mediated contribution to $\langle\sigma v\rangle|_{v\rightarrow 0}$

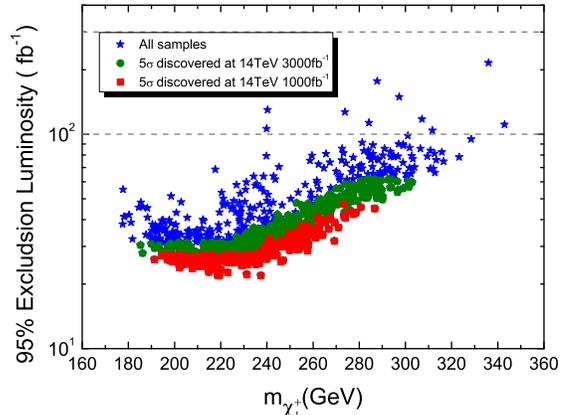

FIG. 3. Required luminosity to exclude the samples of scenario II-S at 95% C.L. at 14-TeV LHC. Samples marked with red square and dark green bullet may be discovered with a luminosity of 1000 fb^{-1} and 3000 fb^{-1} , respectively.

is too small to account for the GCE. We checked numerically that, with the requirement of a correct relic density for the case of $2m_\chi/m_{a_1} < 1$, $\langle\sigma v\rangle|_{v\rightarrow 0}$ is generally smaller than $1.0 \times 10^{-27} \text{ cm}^3/\text{s}$.

C. DM-nucleon scattering: An interesting implication of sizable Z contribution to $\langle\sigma v\rangle_0$ and large $\Gamma_{Z,inv}$ is the DM-nucleon SD scattering cross section σ_p^{SD} . In Fig.2 we show the DM mass versus σ_p^{SD} for II-S samples compared to various experimental upper limits. One can learn that although the current experimental bounds on σ_p^{SD} is less stringent than the spin independent (SI) results, the future XENON-1T and LZ data may be capable of testing most parts of the GCE-favored parameter region. One can also notice that an increased singlino-like DM mass m_χ generally correspond to smaller $\Gamma_{Z,inv}$ and σ_p^{SD} . This is due to the suppressed coupling $g_{Z\chi\chi} \propto (\lambda v/\mu)^2$ as $m_\chi \propto 2(\lambda/\mu)^{-1}\kappa$ increases [21], as well as the moderately suppressed two-body decay phase space since $m_\chi \sim 40 \text{ GeV}$ is quite close to $m_Z/2$. We confirmed these features numerically for II-S samples.

Note that all of our samples have passed the LUX bounds and since scenario II-S requires h_2 to be the SM-like Higgs, one might worry about the possibly large contribution of very light singlet-like CP-even Higgs h_1 to DM-nucleon spin independent (SI) scattering cross section. Nevertheless, the singlet-like h_1 couples to the singlino-like DM with a coupling $g_{h_1\chi\chi} \sim \sqrt{2}\kappa$ [25] and the light singlino-like DM mass $m_\chi \sim 2\kappa(\mu/\lambda)$ requires a small κ . Consequently, $g_{h_1\chi\chi}$ cannot be very large. We checked that our II-S samples have $\kappa \in (0.02, 0.043)$, $m_{h_1} \in (20, 100) \text{ GeV}$, and for very light $h_1 \lesssim 30 \text{ GeV}$ (with only a small number) κ decreases rapidly. Consequently, it is not difficult for scenario II-S to satisfy the direct detection experiment.

D. Test the explanation at 14-TeV LHC: Now we discuss the capability of 14-TeV LHC to test the GCE explanation in NMSSM. In Fig.3 we show the needed luminosity to exclude the II-S samples at 95% C.L. as a function of the lightest chargino mass $m_{\tilde{\chi}_1^\pm}$. For each sample, we choose its most sensitive SR, which is usually SRZc for $m_{\tilde{\chi}_1^\pm} \leq 230$ GeV and SRZd for $m_{\tilde{\chi}_1^\pm} \geq 280$ GeV, and require the corresponding \mathcal{S} (see Sec.II) to be 1.96 to get the exclusion luminosity. Fig.3 indicates that with an integrated luminosity of 100 (200) fb^{-1} , most (all) of the II-S surviving samples will be excluded. In Fig.3 we also use red squares and dark green bullets to indicate samples that may be discovered at 14-TeV LHC with 1000 fb^{-1} and 3000 fb^{-1} luminosities, respectively. As for the benchmark point of scenario II-B (I-B), we find that the exclusion luminosity is 35.2 fb^{-1} (23.7 fb^{-1}) and the discovery luminosity is 950 fb^{-1} (300 fb^{-1}). Note that, if the trilepton signal is combined with the 2-lepton+jets signal of the $\tilde{\chi}_i^\pm \tilde{\chi}_j^0$ associated production processes as done in [52], the needed luminosity may be further reduced.

IV. CONCLUSION

We scanned the NMSSM parameter space by considering various experimental constraints to explain both the GCE and the measured Ωh^2 with a DM satisfying $30 \text{ GeV} \leq m_\chi \leq 40 \text{ GeV}$. We have the following observations: a) The GCE can be explained by the DM annihilation $\chi\chi \rightarrow a_1^* \rightarrow b\bar{b}$ near the resonance region $2m_\chi/m_{a_1} \sim 1$, and a singlino-like DM is more favored than a bino-like DM; b) When $2m_\chi/m_{a_1}$ moderately de-

viates from the resonance, in order to produce the measured relic density, a sizable Z boson contribution to the DM annihilation in the early universe must be present, resulting in the higgsino mass μ upper bounded by about 350 GeV; c) Although the current experimental bounds on DM-nucleon spin dependent scattering cross section σ_p^{SD} is less stringent than the spin independent results, the future XENON-1T and LZ data may be capable of testing most parts of the GCE-favored parameter region; d) Detailed simulations on the $3\ell + E_T^{\text{miss}}$ signal from neutralino/chargino associated production at 14-TeV LHC indicate that the surviving samples can be mostly (completely) excluded at 95% C.L. with an integrated luminosity of 100 (200) fb^{-1} , or a large portion of them may be discovered with an integrated luminosity of 3000 fb^{-1} .

Finally, we have two comments about our discussions. One is that if we slightly relax the constraint from dwarf galaxies, e.g. to be $\langle\sigma v\rangle|_{v\rightarrow 0} \lesssim 2.0 \times 10^{-26} \text{ cm}^3/\text{s}$, we find that our conclusions keep unchanged. The other one is that when we finished this work, a sophisticated analysis of the Fermi-LAT data was performed including an estimate of systematic uncertainties [17, 27]. In such a case, the favored DM mass range becomes heavier and wider than previous discussions. We will keep a close eye on the progress in this direction.

This work was supported by the ARC Center of Excellence for Particle Physics at the Tera-scale, by the National Natural Science Foundation of China (NNSFC) under grant No. 10821504, 11222548, 11305049 and 11135003, and also by Program for New Century Excellent Talents in University.
